

Paclobutrazol-induced Drought Tolerance in Containerized English and Evergreen Oak

Glynn C. Percival and Ali Mohammed Salim AlBalushi

Abstract. The influence of paclobutrazol (PBZ) applied as a foliar spray and root drench on drought tolerance and recovery from drought, of containerized English and evergreen oak was investigated. PBZ treatment induced a suite of physiological adaptations that would allow both species to tolerate drought; more specifically, increased total leaf content of carotenoids (lutein:β-carotene:neoxanthin:α-carotene) and xanthophylls (zeaxanthin:antheraxanthin:violaxanthin), chlorophylls, proline, superoxide dismutase, and catalase. In addition, PBZ strengthened leaf membrane integrity and increased leaf photosynthetic efficiency and light-induced CO₂ fixation before and at the cessation of the drought treatment. Irrespective of species, recovery rates of droughted trees treated with PBZ were 20% to 50% higher than non-PBZ-treated trees. In all cases, control trees (non-PBZ-treated) had the least capacity for recovery. Application of some of the PBZ treatments induced overregulation of newly emerged leaves. Results of this investigation indicate applications of the growth inhibitor PBZ either as a foliar spray or root drench induce a suite of physiological adaptations that confer a useful degree of drought tolerance and aid in the recovery from drought-induced damage. It is suggested that PBZ-induced protection of both English and evergreen oak from damage caused by drought stress is mediated by increased antioxidant enzyme and pigment activities.

Key Words. Carotenoids; chlorophyll fluorescence; chlorophylls; electrolyte leakage; growth inhibitor; proline; *Q. Ilex*; *Quercus robur*; stress enzymes; transplanting.

The establishment of trees after planting in urban environments is difficult because of the harsh environmental conditions that exist. These include soil compaction caused by road surfacing, machinery, and pedestrians (Craul 1994); air and soil pollutants (oxides of S and N, SO₂, polychlorinated biphenyls); heavy metals (Zn, Cu, Cd); atmospheric particulates; ozone; ethylene; deicing salts; and water stress (drought, waterlogging). Such stresses contribute to tree decline through reduced translocation of photosynthates to roots, impaired stomatal function, premature leaf senescence, clogged lenticels, branch dieback, stem/trunk lesions, leaf scorch, tip burn of conifers, and eventual tree death (Percival et al. 2006).

During the first few years of establishment, water is vital to trees for survival. Plant cells are killed or injured by desiccation resulting from moisture lost by transpiration through leaves as the stomata that facilitate photosynthetic gaseous exchange also allow water vapor to escape (Mooney 1982). According to Watson (2001), “maintaining favorable water status is crucial for successful establishment of newly planted trees in the landscape.” Because trees are grown in perfect conditions in nurseries, when they are planted outside into harsher urban environments, it is difficult for a tree to

adapt. Consequently, the percentage of survival after outplanting has often been low. Improving hardiness against drought before outplanting may ensure greater postplanting survival of newly planted trees. This in turn will reduce labor and replacement cost. Hence, finding exogenous chemicals that improve a plant’s stress tolerance may save trees during severe drought conditions (Still and Pill 2004).

Paclobutrazol (PBZ) is a triazole-based plant growth regulator developed by Imperial Chemical Industries, now known as Zeneca and sold under the trade name “Cultar,” for use on fruit trees and “Bonsi” for use on ornamentals in the United Kingdom (Fletcher et al. 1986). “Cultar” is formulated in Europe as a suspension concentrate that can be applied as a spray or soil drench treatment. The retardant activity is not accompanied by phytotoxicity or scorch, even when applied at higher rates (Dalziel and Lawrence 1984). The principal mode of action of PBZ is through inhibition of gibberellin biosynthesis (Dalziel and Lawrence 1984). PBZ is readily taken up through the roots, stems, and leaves but is transported almost exclusively in the xylem to its site of action, the subapical meristem, where it has a persistent effect (Anon, 1984).

Paclobutrazol has been shown to reduce the shoot growth of many tree species (Davis et al. 1985) and is commonly used on trees under utility lines (Watson 1996). According to Watson (2001), the application of PBZ as soil drench treatment at planting time may be able to stimulate root elongation and reduce water stress of trees after transplanting. A further study by Watson (2001) reported that after 10 weeks of drought stress, stem water potential of elms treated with PBZ was the same as the well-watered controls. Indeed, a number of workers conclude that PBZ can be used as a pretreatment to protect plants against drought and increase the percentage of plant survival after transplanting in semiarid climatic conditions (Asare-Boamah et al. 1986; Fletcher et al. 2000; Marshall et al. 2000). In most cases, PBZ-induced drought tolerance has been associated with a decrease in transpiration, plant height, biomass, and leaf area and an increase in stomatal resistance.

Because applications of PBZ increased the stress tolerance of woody plants, it can be suggested that pretreatment application with PBZ would cause an increase in the stress tolerance of other trees species widely planted into urban environments. Such a response may reduce outplanting losses with limited capital investment and only small adjustment to management procedure, the cost of which is negligible compared with the risk of tree death.

The aims of this study are:

- To determine the effectiveness and feasibility of PBZ applied as a root drench and foliar spray to improve the drought tolerance of two urban tree species, evergreen oak (*Quercus ilex*) and English oak (*Q. robur*);
- To investigate the concentration conferring maximal resistance to and recovery from drought-induced stress; and
- To evaluate PBZ-induced alterations to plant physiology that could contribute to drought tolerance.

MATERIALS AND METHODS

Plant Material

Two plant species were selected for experimental purposes: evergreen oak (*Quercus ilex*) and English oak (*Q. robur*). Both species are commonly planted into UK urban environments and provide forms with contrasting drought capabilities. Four-year-old cell-grown stock approximately 90 cm (36 in) high \pm 8 cm (3.2 in) were obtained from a commercial supplier (Alba Trees, Lower Winton, East Lothian, UK). Six months before experiments, trees were potted into 4.5 L (1.17 gal) plastic pots filled with soil (loamy texture, 24% clay, 45% silt, 31% sand, 3.1% organic carbon, pH 6.2) supplemented with the controlled-release nitrogen-based N:P:K (29:7:9) fertilizer, Bartlett BOOST (The Doggett Corp., Lebanon, NJ) at a rate of 1 g/kg soil. After potting, trees remained outdoors subject to natural environmental conditions and watered as required. In early April 2005, trees were moved to a

polythene tunnel to protect against possible spring frosts. As soon as the initial symptoms of bud burst were observed, i.e., leaf emergence (late April), trees were placed under glasshouse conditions ($22^{\circ}\text{C} \pm 2^{\circ}\text{C}$ [$71.6^{\circ}\text{F} \pm 35.6^{\circ}\text{F}$]) supplemented with 400 W high-pressure sodium lamps providing a photoperiod of 16hr light/8hr dark and minimum $250 \mu\text{mol}/\text{m}^{-2}/\text{s}^{-1}$ photosynthetically active radiation (PAR) at the tree crown until PBZ treatments began.

Paclobutrazol Application

Paclobutrazol treatments were applied when both tree species were in full leaf (2 May 2005). Foliar sprays of PBZ were applied until runoff using a handheld sprayer. As a root drench, PBZ was applied to the substrate surface until fully saturated, i.e., when liquid was seen emerging from the base of the pots. Drenching with distilled water served as the control. Concentrations of PBZ applied were: 1) control (no application of PBZ); 2) 2 mL (0.06 fl oz) PBZ per liter water applied as spray until runoff; 3) 4 mL (0.12 fl oz) PBZ per liter water applied as spray until runoff; 4) 5 mL (0.15 fl oz) PBZ per 250 mL (7.5 fl oz) water applied as root drench to achieve a concentration of 0.25 g (0.01 oz) PBZ per 2.5 cm (1 in) girth, approximately 50 mL (1.5 fl oz) per pot; and 5) 10 mL (0.3 fl oz) PBZ per 250 mL (7.5 fl oz) water applied as root drench to achieve a concentration of 0.50 g (0.02 oz) PBZ per 2.5 cm (1 in) girth, approximately 50 mL (1.5 fl oz) per pot.

Plants were left for 2 weeks under glasshouse conditions to permit absorption and uptake of PBZ. During this period, plants were watered as required, generally every 3 days. At week 2, after PBZ treatment (16 May 2005), measurements of plant physiology were made.

Drought Treatment and Experimental Design

Plants were subjected to drought by the cessation of watering for 3 weeks under glasshouse conditions. At week 3 (6 June 2005), a number of physiological measurements were made on leaf tissue as measures of tree vitality. Immediately after measurements, trees were watered as required and placed outdoors subject to natural weather conditions and recovery rates measured over the next 9 weeks at three weekly intervals (27 June, 18 July, 8 August). The experimental design used was a completely randomized block design in which pots were rerandomized on a weekly basis. Ten trees per treatment were used at 0.75 m (0.83 ft) spacings to prevent competition for light.

Tree Vitality Measurements

All tree vitality measurements were taken on leaf material present on the plant at the initiation of the experiment (existing leaves). During recovery from drought, new leaf formation was observed at approximately weeks 6 to 7 on both control and PBZ-treated surviving plants. No tree vitality

measurements were taken on any newly formed leaf tissue, i.e., new leaves not present at the time of PBZ application. At each sampling date, five leaves per tree were used for chlorophyll fluorescence and chlorophyll content measurements randomly selected throughout the crown. Leaves were then tagged to ensure the same leaf was measured throughout the study.

Chlorophyll Fluorescence

Chlorophyll fluorescence was used as a measure of damage to the leaf photosynthetic system. Leaves were adapted to darkness for 30 min by attaching light exclusion clips to the leaf surface and chlorophyll fluorescence was measured using a HandyPEA portable fluorescence spectrometer (Hansatech Instruments Ltd., King's Lynn, UK). Measurements were recorded up to 1 sec with a data acquisition rate of 10 μ s for the first 2 ms and 1 ms thereafter. The fluorescence responses were induced by a red (peak at 650 nm) light of 1500 μ mol/m²/s⁻¹ PAR intensity provided by an array of six light-emitting diodes. A performance index (PI) based on an equation that combines the relationship of calculated relative number of reaction centers (RC) per energy absorbed (ABS) and then multiplied by two expressions describing the yields of light trapping (ϕ_{po}) and subsequent electron transport (Ψ_0), i.e., $RC/ABS \times \phi_{po}/(1 - \phi_{po}) \times \Psi_0/(1 - \Psi_0)$; Clark et al. 1998, 2000; Percival and Fraser 2001) was used to quantify any effects on leaf tissue. PI values have been shown to be a highly sensitive measure of leaf photosynthetic activities and provide an indirect measure of plant vitality. PI values were automatically calculated by the HandyPEA.

Leaf Chlorophyll Content

A Minolta chlorophyll meter SPAD-502 (Spectrum Laboratories, Inc., Plainfield, IL) was used. Chlorophyll was measured at the midpoint of the leaf next to the main leaf vein. Calibration was obtained by measurement of absorbance at 663 and 645 nm in a spectrophotometer (PU8800 Pye Unicam, Cambridge, UK) after extraction with 80% v/v aqueous acetone (regression equation = $6.01 + 0.055x$; r^2 adjusted = 0.90, $P < 0.01$) (Lichtenthaler and Wellburn 1983).

Photosynthetic CO₂ Fixation

Light-induced CO₂ fixation (P_n) was measured in two pre-darkened (20 min) fully expanded leaves per tree near the top of the canopy (generally approximately the fourth leaf from the apex) using an Infra Red Gas Analyser (LCA-2 ADC; ADC Ltd, Hoddesdon, Herts, UK). The irradiance on the leaves was 700 to 800 μ mol/m² PAR saturating with respect to P_n ; the velocity of the airflow was 1 mL/s⁻¹/cm² leaf area. Calculation of the photosynthetic rates was carried out according to Von Caemmerer and Farquhar (1981). All photosynthetic measurements were taken in the early morning be-

tween 8:00 A.M. and 10:00 A.M. on clear or partly cloudy days.

Leaf Necrosis

Leaf necrosis was assessed visually. Each tree was rated on a 0 to 5 rating scale using a visual indexing technique and ratings on the scale: 0 = no necrosis observed; 1 = less than 5% of leaves affected and no aesthetic impact; 2 = 5% to 20% of leaves affected with some yellowing but little or no defoliation; 3 = 21% to 50% of leaves affected, significant defoliation and/or leaf yellowing; 4 = 51% to 80% of leaves affected, severe foliar discoloration; and 5 = 81% to 100% of foliage affected with 90% to 100% defoliation.

Leaf Electrolyte Leakage

Quantitative drought damage to leaf tissue was assessed by measuring electrolyte leakage of entire leaves (two leaves per tree) at each sampling date. Excised leaves were placed in 50 mL (1.5 fl oz) universal bottles containing 30 mL (0.9 fl oz) distilled water and gently shaken by hand. Samples were stored at 22°C (71.6°F) for 24 hr in darkness before conductivity measurements using a Jenway conductivity probe and M4070 m (BDH, Leicestershire, Loughborough, UK). Total solute leakage was obtained by autoclaving for 1 hr at 121°C (249.8°F) and 0.103 MPa. Results are presented as percent solute leakage after 24 hr (McKay 1992)

Carotenoids

Carotenoids (lutein, β -carotene, neoxanthin, α -carotene, zeaxanthin, antheraxanthin, violaxanthin) were analyzed using a high-performance liquid chromatography (HPLC) system (Schindler and Lichtenthaler 1994). Leaf samples were excised from trees and immediately placed in liquid nitrogen. Fifty leaf samples per treatment, i.e., five leaves per tree, were taken. Pigment analysis was performed the next day. Pigments were extracted from leaves with 100% aqueous acetone (quartz sand mortar) and separated and quantitatively determined by reverse-phase HPLC applying a Nucleosil C₁₈ column (particle size 4 μ m). The solvent systems for the combined isocratic and gradient separation and quantification were acetonitrile-methanol-0.2 M tris/HCL buffer and methanol-hexane (Lichtenthaler et al. 1992).

Superoxide Dismutase Activity

Superoxide dismutase (SOD) activity was based on the method described by Kraus and Fletcher (1994). In summary, extracts were prepared at 4°C (39.2°F) by homogenizing 0.2 g (0.07 oz) of leaf tissue (generally three leaves per plant) in 4 mL (0.12 fl oz) of 0.1 M Na₂HPO₄/NaH₂PO₄ buffer (pH 7) with a mortar and pestle and centrifuged at 16,000 \times g for 10 min. The supernatant was filtered through Watman paper (No. 1) (Sigma-Aldrich, Poole, UK) and 1 mL (0.03 fl oz) was applied to a Pharmacia PD-10 chromatography column (Waters HPLC Solutions, Centennial Park, Elstree, Hertfordshire, UK) containing Sephadex G-250 (Waters HPLC Solu-

tions) equilibrated with 50 mM Na₂CO₃ buffer (pH 10.2) to remove low-molecular-weight components and exchange the buffer. The assay was performed using 0.1 mM diethylenetriaminepentaacetic acid in the reaction mixture and the subsequent increase in absorbance at 550 nm followed on a spectrophotometer (PU8800 Pye Unicam) equipped with a kinetics module for 6 min at 24°C (75.2°F).

Catalase Activity

A total of 0.3 g (0.11 oz) of foliar tissue (generally five leaves per plant) were homogenized in 5 mL (0.15 fl oz) of 0.2 M Tris-Cl⁻ (buffer pH 7.8) containing 0.13 mM EDTA and 80 µM soluble polyvinylpyrrolidone with a Polytron homogenizer (Glen Mills, Clifton, NJ) for 30 sec on ice and centrifuged at 3000 × *g* for 10 min. Catalase activity was determined by following the consumption of hydrogen peroxide (extinction coefficient 39.4 mm⁻¹/cm⁻¹) at 240 nm for 2 min. The reaction mixture contained 2 mL of 100 mM Na₂HPO₄/NaH₂PO₄ buffer (pH 6.5) and 50 µL of plant extract and the reaction was initiated by adding 10 µL of 30% (w/v) hydrogen peroxide.

Proline

Leaf samples (1 g [0.035 oz]) were extracted with 3% sulphosalicylic acid. Extracts (2 mL [0.06 fl oz]) were held for 1 hr in boiling water by adding 2 mL (0.06 fl oz) ninhydrin and 2 mL (0.06 fl oz) glacial acetic acid after which cold toluene (4 mL [0.12 fl oz]) was added. Proline content was measured by a spectrophotometer (Shimadzu UV 1601; Shimadzu UK, Milton Keynes, Buckinghamshire, England) at 520 nm and calculated as µg/g dry leaf weight against standard proline.

Plant Height and Leaf Mean Leaf Area

At the cessation of the experiment, trees were destructively harvested and height recorded by measuring the distance from the tip of the leading apical shoot to the soil surface. Mean leaf size was calculated by quantifying total leaf area per tree using a Delta-T leaf area meter (Delta-T Devices, Cambridge, UK) and dividing by the total number of leaves per tree.

Statistical Analysis

Data for each species was analyzed independently by one-way analysis of variance using the Genstat V program (Committee of the Statistics Department, Rothamsted Experimental Station, Harpenden, Hertfordshire, UK) for Windows. Before the analysis, data were examined for normality and homogeneity of variance (Levene 1960) and data were transformed [$\log(y + 0.5)$] when necessary. When significant differences occurred, the means were separated by least significant difference test ($P < 0.05$). Survival recorded as percentage and visual leaf necrosis were analyzed after appropriate statistical transformation ($\arcsin[x^{0.5}]$). Because measurements over time were obtained from the same plant, the

relationship between chlorophyll fluorescence and SPAD readings over time after PBZ treatments was quantified using repeated measures analysis (quadratic regression).

RESULTS

Basal Alterations to Plant Physiology 2 Weeks After Paclobutrazol Application

Irrespective of concentration applied and mode of application (foliar spray or root drench), PBZ induced a number of significant ($P < 0.05$) changes in whole plant physiology of both English and evergreen oak compared with non-PBZ-treated controls (Tables 1 and 2). Leaf membrane integrity as assessed by leakiness of leaf tissue was reduced by 14% to 34%, whereas PI and Pn was increased by 3 to 17 and 3% to 18%, respectively, in both test species (Tables 1 and 2). In all cases, PBZ-treated plants had a higher leaf content of total carotenoids and chlorophylls with levels increased by 14 to 25 and 12% to 29%, respectively, compared with non-PBZ-treated controls. Similar percentage increases were recorded in the leaf content of carotenoids (lutein:β-carotene:neoxanthin:α-carotene) and xanthophylls (zeaxanthin:antheraxanthin:violaxanthin), although no effects were found on their ratios (Tables 1 and 2). No PBZ-induced effects were found on the ratio of chlorophyll a/b in comparison with control plants. Irrespective of species, PBZ-treated plants had 4% to 20%, 8% to 31%, and 9% to 37% more proline, superoxide dismutase, and catalase, respectively, than controls. No symptoms of phytotoxicity were observed at week 2 after PBZ application, i.e., no leaf necrosis observed on foliage of evergreen oak and leaf necrosis values ranging from 0 to 0.4 in (0 to 0.16 cm) English oak (Tables 1 and 2).

Chlorophyll Fluorescence, Light-induced Photosynthetic CO₂ Fixation, Membrane Integrity, Leaf Chlorophyll Content, and Necrosis at Week 3 Postdrought Treatment

Irrespective of concentration or mode of application (foliar spray, root drench), in all cases, PBZ protected both English and evergreen oak from injury resulting from drought as manifest by reduced mortality in PBZ-treated trees compared with non-PBZ-treated controls (Tables 3 and 4). Such a response was particularly pronounced in English oak in which all PBZ-treated trees survived a 3-week drought period compared with controls in which a significantly lower 20% survival rate was recorded (Table 3). In the case of English oak, PI values as a measure of leaf photosynthetic efficiency, Pn, and leaf chlorophyll content were all significantly ($P < 0.05$) higher than non-PBZ-treated controls (Table 3). A similar response was recorded in evergreen oak in which in all cases, PI, Pn, and leaf chlorophyll content were always higher than non-PBZ-treated controls, if not significantly so in every instance. Such a response indicates reduced damage to the leaf

PBZ = paclobutrazol.

photosynthetic system and greater structural integrity of the chlorophyll molecule at the cessation of the drought period. Leaf electrolyte leakage as a measure of drought-induced damage to cellular membrane integrity was reduced by 49% to 67% in the case of PBZ-treated English oak and by 28% to 48% in the case of PBZ-treated evergreen oak compared with control values (Tables 3 and 4). Similarly, visual leaf necrosis was reduced by 51% to 56% in the case of PBZ-treated English oak and by 21% to 37% in the case of PBZ-treated evergreen oak compared with control values (Tables 3 and 4). In most cases, these reductions were significant ($P < 0.05$) from controls (Tables 3 and 4).

Effects of Paclobutrazol on Drought Recovery Rates

The pattern of recovery over the next 9 weeks after 3 weeks of drought on PI, leaf necrosis, chlorophyll content, and cel-

lular electrolyte leakage is shown for English and evergreen oak (Tables 5 and 6). In addition, the pattern of recovery is shown diagrammatically for both species with respect to leaf chlorophyll content (Figures 1 and 2). Irrespective of treatment (with or without PBZ), all four parameters began to recover in surviving trees after the start of watering. Consequently, the pattern of recovery was quantified by quadratic regression analysis to compare the rate of recovery over the next 9 weeks (Tables 5 and 6). Irrespective of species, all PBZ-treated trees were the most capable of recovery as reflected by higher regression values with respect to PI and leaf chlorophyll recovery and lower regression values with respect to leaf necrosis and cellular electrolyte leakage (Tables 5 and 6). Such responses in PBZ-treated trees are associated with enhanced recovery of leaf photosynthetic integrity, improved photosynthetic efficiency, reduced degradation of the chlorophyll molecule structure, and enhanced membrane in-

mode of application (foliar spray or root drench) and concentration applied. None of the treatments used in this investigation altered the ratio of chlorophyll *a*:*b* in English (2.953:1.9) or evergreen oak (3.14–3.38; data not shown).

Plant Height and Mean Leaf Size

During the drought recovery phase, new leaf formation was observed at approximately weeks 4 to 6 on both control and PBZ-treated surviving trees. Distinct symptoms of overregulation, i.e., stunted leaf formation were visibly noticeable in plants treated with 4 mL (0.12 fl oz) PBZ per liter as a foliar spray and PBZ as a root drench at both 5 and 10 mL (0.15 and 0.3 fl oz) per 250 mL (7.5 fl oz) water (Table 7). Indeed, a significant ($P < 0.05$) reduction in leaf size and height was recorded in both evergreen and English oak at the cessation of the experiment after these treatments. Trees sprayed with 2 mL (0.06 fl oz) PBZ per liter had a smaller mean leaf size and height than controls but not significantly so.

DISCUSSION

Results of this study showed that pretreatment of English and evergreen oak with PBZ as a foliar spray or root drench induced a suite of physiological adaptations that would allow both species to tolerate drought after transplanting. Such a

Figure 1. Time course recovery of leaf chlorophyll content (SPAD values) of evergreen oak (*Quercus robur* L.) placed outdoors after a 21-day drought period. Controls, values mean of mean of two trees, five leaves per tree. ▼ = Control; ▲ = 2 mL PBZ foliar spray; ● = 4 mL PBZ foliar spray; + = 5 mL PBZ root drench; ◆ = 10 mL PBZ root drench.

response is particularly noticeable in English oak in which drought-related mortality rates were reduced by 80%. More specifically, PBZ strengthened leaf membrane integrity, increased leaf PI, Pn, total leaf content of carotenoids (lutein:β-carotene:neoxanthin:α-carotene) and xanthophylls (zeaxanthin:antheraxanthin:violaxanthin), chlorophylls, proline, SOD, and catalase. No marked differences were observed after application of PBZ as a root drench or foliar spray, although previous research suggests PBZ application has a greater efficiency as a substrate drench than as spray treatment (Davis et al. 1988; Bañón et al. 2002).

One of the initial plant responses to drought is stomatal closure to conserve transpirational water loss. Such a response can be highly detrimental to the leaf photosynthetic system as a result of the prevention of light energy conversion into electrochemical energy caused by low CO₂ concentrations within the leaf tissue, in turn resulting in the production of high-energy reactive oxygen species (ROS) such as superoxide and singlet oxygen (Lawlor 2001). Singlet oxygen and other ROS are highly toxic compounds that cause acute membrane damage. Unchecked ROS can be converted into hydrogen peroxide (bleach), which diffuses over much greater distances and causes further oxidative damage such as chlorophyll bleaching and cellular membrane destruction. To minimize the effects of oxidative stress induced by drought stress, plants have evolved a complex antioxidant system, which is composed of low-molecular mass antioxidants such

as carotenoids as well as ROS-scavenging enzymes such as SOD and catalase (CAT; Apel and Hirt 2004). Relatively higher activities of ROS-scavenging enzymes have been reported in stress-tolerant genotypes when compared with susceptible ones, suggesting that these antioxidant enzymes plays an important role in plant tolerance against environmental stresses such as salinity and drought (Apel and Hirt 2004). In the current study, a significant increase in leaf SOD and CAT activity was observed in both PBZ-treated English and evergreen oak. The function of SOD is to scavenge superoxide in the chloroplast and catalyze the first step in the detoxification of active oxygen to H_2O_2 . H_2O_2 is then scavenged by catalase resulting in the dismutation of H_2O_2 to water and oxygen. Likewise, carotenoids (carotenes and xanthoylls) function as protective photooxidative pigments responsible for the quenching of chlorophyll excited states, singlet oxygen, and interception of deleterious free oxygen and organic radicals caused by drought-induced photoinhibition (Lawlor 2001). Enhanced leaf concentrations of carotenes and xanthoylls recorded in PBZ-treated plants before the start of the drought treatment imposed in this investigation would be important contributors to reducing drought-induced photoinhibitory damage to plant cellular membranes and the photosynthetic system (Kraus and Fletcher 1994).

In this experiment, an increase in the amino acid proline in plants treated by PBZ was observed. The function of proline is to reduce the osmotic potential so that the water potential gradient favors water uptake and therefore the plant can maintain turgor, for example, under drought or salinity conditions. The advantage of osmotic adjustment to the plant is that water potential across cells and tissues is maintained against a fall in water potential during drought, in turn preventing or reducing whole plant turgor. In addition, it is suggested that proline may also protect protein configurations during dehydration (Fernandez et al. 2006). Consequently, an increase in leaf proline concentration would permit a more favorable water uptake under water stress conditions improving the adaptation of plants to drought conditions. The association between increased proline concentration and tolerance to drought has been shown elsewhere (De Ronde et al. 2000; Ain-Lhout et al. 2001; Jiang and Huang 2001; Ehmedov et al. 2002; Yamada et al. 2005). Likewise, exogenously applied proline has been shown to significantly increase the stress tolerance of a broad range of plants (Van Swaaij et al. 1985; Songstad et al. 1990; Santarius 1992). With the exception of these experiments, few studies have observed the direct effect of PBZ on proline accumulation within plant tissue, although a number of examples exist showing a subsequent increase in leaf protein (to include proline) concentrations post PBZ application (Sankhla et al. 1992; Kraus and Fletcher 1994).

The chlorophyll fluorescence PI value is a measure of leaf photosynthetic efficiency and subsequently provides an indirect measure of tree vitality (Clark et al. 1998, 2000). A decline in this value is a sensitive indicator of photoinhibitory damage caused by a wide range of environmental stresses such as salinity, drought, and ozone exposure. After exposure to 3 weeks of drought, the PI value in the PBZ-treated trees was substantially higher than non-PBZ-treated controls. Thus, the plants treated with PBZ were found to be from 60% to greater than 100% more efficient photosynthetically. The maintenance of relatively high fluorescence values in PBZ-treated plants under stress has been observed in previous studies (Pinhero and Fletcher 1994). Increased photosynthetic efficiency permits increased metabolic activity within the plant such as synthesis of sugars, amino acids, proteins, nucleic acids, and lipids, essential for the growth and repair of damaged tissue. If the photosynthetic system is impaired, then the carbohydrates required for repair and growth cannot be produced. Higher PI values in PBZ-treated plants indicate less damage to the leaf photosynthetic system in turn manifest by a greater ability to repair damaged tissue, grow, and survive after the cessation of drought (Percival et al. 2006).

Leakiness of leaf tissue, determined from electrolyte leakage, indicated that cellular membrane integrity was damaged more rapidly in non-PBZ-treated controls compared with PBZ-treated plants at the cessation of 3 weeks of drought.

Stem electrolyte leakage indicates tissue damage resulting in the loss of cell membrane semipermeability (Cameron and Dixon 1997). The principle of electrolyte leakage is that the movement of cell contents to and from cells is controlled mainly by the structural proteins present at points along the lipid bilayer of the cell membrane. When healthy plant tissue is immersed in ion-free water, there is a slight leakage into the surrounding water, which can be detected and quantified using a conductivity meter. If the cell membrane is ruptured or the transmembrane protein pumps impaired, the cell contents leak at a greater rate. Indeed, levels of damage to plant tissue caused by drought have been investigated using electrolyte leakage (Martin et al. 1987; McKay 1992). In all cases, PBZ-treated plants maintained a lower degree of electrolyte leakage, i.e., higher degree of membrane integrity, than the respective controls at the cessation of 3 weeks of droughts.

In addition to reduced damage at the cessation of 3 weeks of drought, recovery rates of PBZ-treated plants ranged from 20% to 50% higher than non-PBZ-treated trees. Few investigations have recorded the potential of PBZ to aid in the recovery of urban trees from drought damage. Indeed, most physiological parameters recorded in this investigation as measures of tree vitality (PI, leaf necrosis, leaf chlorophyll content, electrolyte leakage) were comparable with original levels at day 0 by week 4 to 6 postrecovery indicating regeneration and full functioning of the leaf photosynthetic structure and chlorophyll molecule. Gilley and Fletcher (1997) observed that almost no decrease in chlorophyll concentration in wheat treated with PBZ compared with a loss of 28% of total chlorophyll after 3 hr at 50°C (122°F) heat stress in the non-PBZ-treated plants. Recently, in a study by Still and Pill (2004) they showed that 'Marglobe' tomato plants treated with PBZ either by soaked seeds or sprayed plants have more stress tolerance compared with nontreated plants. They also reported that treated 'Marglobe' tomato plants had lower loss of total chlorophyll during the 10-day poststress recovery period compared with nontreated controls. The importance of rapid recovery from stress has been shown elsewhere. Genotypes that rebound to original or near original physiological levels most likely survive and tolerate drought episodes compared with those that do not or are slower to recover (Aguilera et al. 1997; Bauerle and Dudley 2003). In all cases, control trees (non-PBZ-treated) had the least capacity for recovery in which PI, leaf necrosis, leaf chlorophyll content, and electrolyte leakage were still 15% to 25% lower at the cessation of the experiment than original basal levels recorded at day 0.

Overregulation of growth as manifest by stunted crinkled foliage is a major disadvantage when using growth inhibitors such as PBZ. In many cases, overregulatory effects on growth can last 2 to 3 years. In this experiment, three of the four

treatments, although increasing the drought tolerance and recovery of both English and evergreen oak, resulted in a statistically significantly smaller trees in terms of height and mean leaf size. Such an effect is undesirable when planting trees into amenity environments where aesthetics are a major factor regarding tree selection.

In conclusion, water stress after planting is generally recognized as a major factor resulting in death of newly transplanted trees (Gilbertson and Bradshaw 1990). Results of this investigation indicate applications of the growth inhibitor PBZ either as a foliar spray or root drench induce a suite of physiological adaptations that confer a high degree of drought tolerance and aid in the recovery from drought-induced damage. It is suggested that PBZ-induced protection of both English and evergreen oak from damage caused by drought stress is mediated by increased antioxidant enzyme and pigment activities.

Résumé. L'influence du paclobutrazol par vaporisation foliaire et par mouillage du sol a été étudiée chez des chênes anglais et des chênes toujours-verts en pot en regard de la tolérance à la sécheresse

et de la reprise suite à une sécheresse. Le traitement au paclobutrazol a induit une suite d'adaptations physiologiques qui pourraient permettre à ces deux espèces de tolérer la sécheresse. Plus spécifiquement, cela a accru le contenu foliaire total en caroténoïdes (lutéine: β -carotène:néoxanthine: α -carotène), en xanthophylles (zeaxanthine:antheraxanthine:violaxanthine), en chlorophylle, en proline, en superoxyde dismutase et en catalase. De plus, le paclobutrazol a renforcé l'intégrité de la membrane, a accru l'efficacité de la photosynthèse foliaire et la fixation induite par la lumière du CO₂ préalablement ainsi qu'à la fin du traitement de sécheresse. En dépit de l'espèce, le taux de reprise des arbres ayant subi une sécheresse était de 20 à 50% plus élevé pour ceux traités avec le paclobutrazol que ceux non traités. Dans tous les cas, les arbres témoins (ceux non traités au paclobutrazol) avaient la plus faible capacité de recouvrement. L'application de certains traitements au paclobutrazol a induit au delà de la normale la formation de nouvelles feuilles. Les résultats de cette étude indiquent que les applications du régulateur de croissance paclobutrazol, que ce soit par vaporisation foliaire ou par mouillage sur le sol, induisent une suite d'adaptations physiologiques qui confèrent un degré utile de tolérance à la sécheresse et qui aident le recouvrement des arbres suite à des dommages par la sécheresse. Il est suggéré que la protection induite par le paclobutrazol contre les dommages par la sécheresse chez le chêne anglais et le chêne toujours-vert se fait via un accroissement de l'activité des enzymes antioxydants et des pigments.

Zusammenfassung. Hier wurde der Einfluß von Paclobutrazol (PBZ), als Blattspray und Wurzelbehandlung aufgetragen, bei trockenheits-toleranten und sich von Trockenheit erholenden, getopften Englischen und Immergrünen Eichen untersucht. Die Paclobutrazol führte zu einer Folge von physiologischen Anpassungen, die beiden Spezies ermöglichen würde, die Trockenheit zu überstehen. Genauer gesagt: gestiegener totaler Anteil von Carotinoiden und Xanthophyll im Blatt, Chlorophyll, Prolin, superoxyde Dismutase und Katalase. Zusätzlich stärkte PBZ die Blattmembranintegrität, verstärkte die Blattphotosynthese-Effizienz (PI) und die licht-induzierte CO₂-Fixation vor und am Ende der Trockenheitsbehandlung. Unabhängig von der Spezies lagen die Erholungsraten der trockenheits-gestressten Bäume nach der PBZ-Behandlung um 20-50% höher als bei den unbehandelten Bäumen. In allen Fällen hatten die Kontrollbäume die schlechtesten Erholungschancen. Die Applikation bei einigen PBZ-Behandlungen führte zu einer Überregulierung bei den neuen Blattaustrieben. Die Resultate dieser Untersuchung zeigen, dass eine Applikation des Wachstumshemmers PBZ entweder als Blattspray oder als Wurzelbehandlung in der Folge zu physiologischen Anpassungen führt, die einen nützlichen Grad an Trockenheitstoleranz gewährt und hilft bei der Erholung nach Trockenheitsschäden. Wir unterstellen, dass der durch PBZ herbei geführte Schutz von Englischen und Immergrünen Eichen begleitet wird durch erhöhte Antioxidations-Rate und Pigment-Aktivität.

Resumen. Se investigó la influencia de paclobutrazol (PBZ), aplicado como spray foliar y al suelo, sobre la tolerancia y recuperación a la sequía de dos especies de encinos en contenedor. El tratamiento con PBZ indujo un paquete de adaptaciones fisiológicas que permitiría la tolerancia a la sequía de las dos especies. Más específicamente incrementaron el contenido total en la hoja de carotenoides (lutéine: β -carotène:néoxanthine: α -carotène) y xanthophylls (zeaxanthine:antheraxanthine:violaxanthine), chlorophylls, proline, superoxyde

dismutase y catalase. Además PBZ fortaleció la integridad de la membrana foliar, incrementó la eficiencia fotosintética (PI) e indujo la fijación de CO_2 (P_n), antes y en la cesación del tratamiento de sequía. Independiente de las especies, las tasas de recuperación de los árboles a la sequía tratados con PBZ fueron 20 – 50% más altas que los árboles no tratados. En todos los casos los árboles de control (no tratados con PBZ) tuvieron menor capacidad de recuperación. La aplicación de algunos tratamiento con PBZ indujo la sobre regu-

lación de hojas recién emergidas. Los resultados de esta investigación indican que las aplicaciones del inhibidor del crecimiento PBZ, bien sea como spray foliar a al suelo, inducen un serie de adaptaciones fisiológicas que confieren un grado útil de tolerancia a la sequía y ayudan en la recuperación de los daños por la misma. Se sugiere que el PBZ indujo la protección de los encinos del daño causado por el estrés de la sequía y es mediado por el incremento de las actividades de enzimas y pigmentos antioxidantes.
